

Draw surface brightness profiles of manga dr14 & dr15, using SDSS images, in order to find out the break position

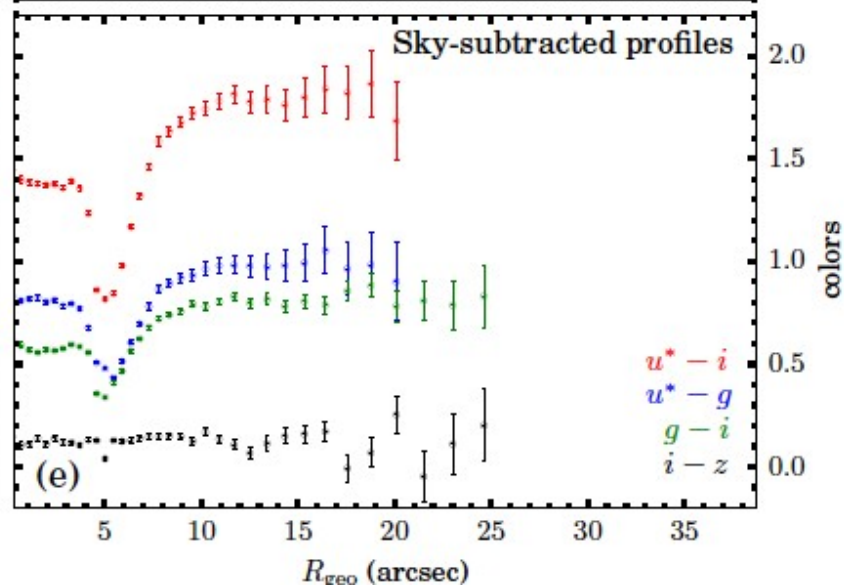

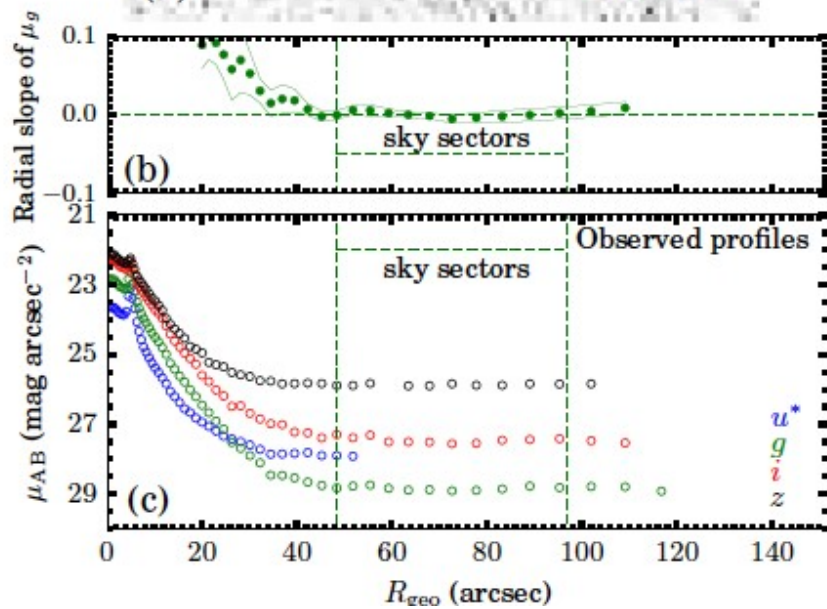

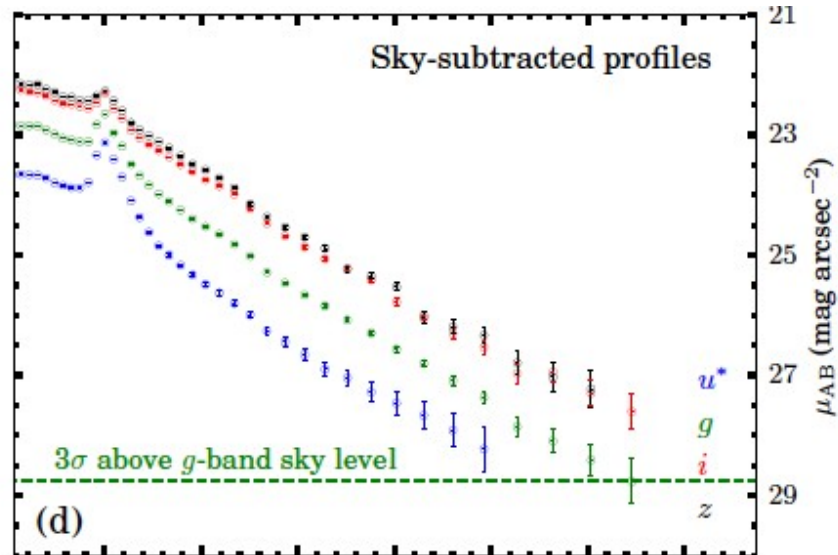

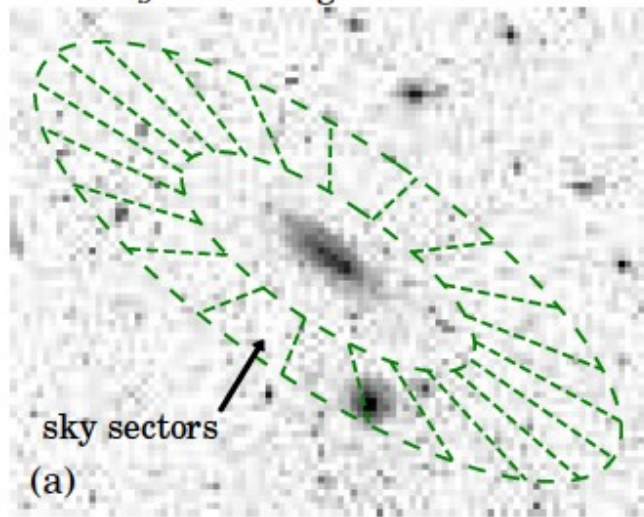

- Step 1: select criteria (total: 709)
  - TType>0 , 或 TType≤0 但是为 S0 的概率大于 90% 的星系，肉眼除去 IFU 中同时存在多个星系的情况 ( 并合、观测目标不符合要求等 )。
  - Re 处轴比  $b/a > 0.5$
  - 受前景星污染影响较小。
- Step 2: use SExtractor to create mask
  - check the mask in avoid of deviding a galaxy into several
- Step 3: meter the galaxy with pyraf
  - x0, y0, ellipticity, position angle, Re : from Manga drpall
  - All parameters are fixed

- Step 4:deduct the background intensity
  - $5 \text{ Re-}5 \sim 5\text{Re}+10$
  - 15 parts

*g*-band image of VCC802

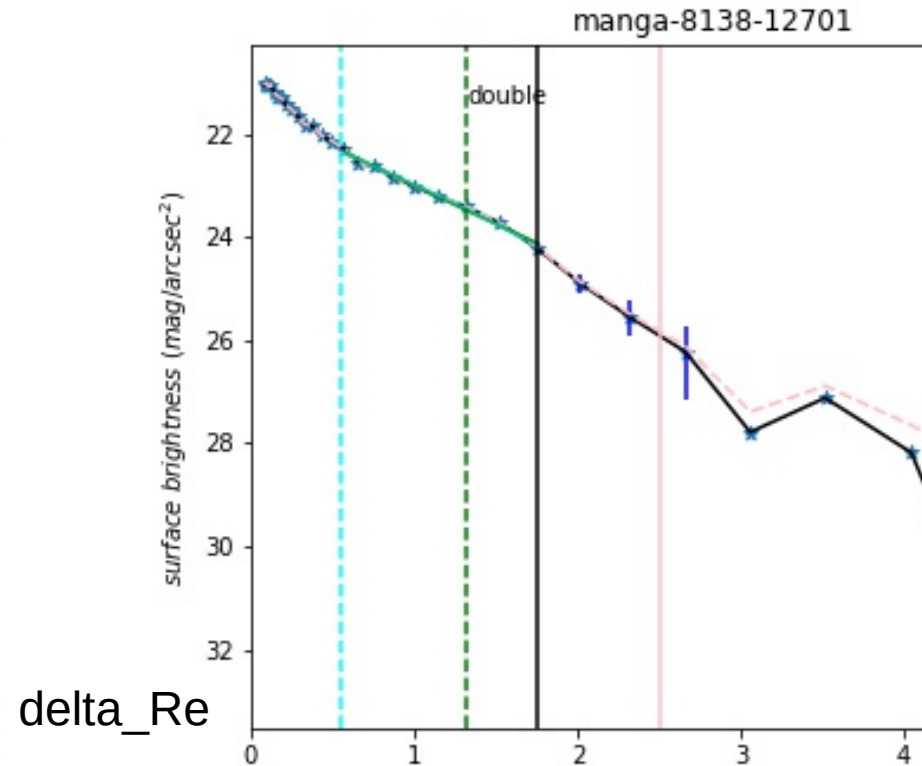

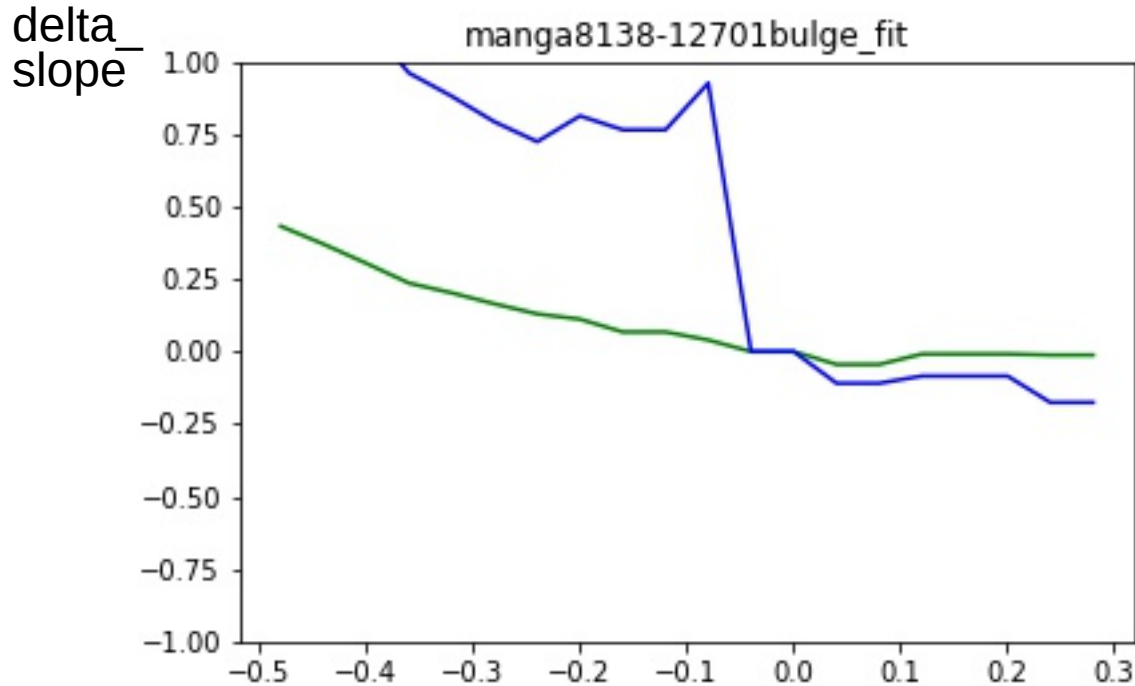

- Step 5: draw the radial-surface brightness profile
  - Error bar: poisson noise & error from background

these numbers we measured the value of the sky and its standard deviation in a total of 15–20 regions of  $N_{\text{region}}$  pixels each around the position of the galaxy. If we now define  $\langle \sigma_{\text{sky}} \rangle$  and  $\langle \sigma_{\text{sky}} \rangle^2$  as the mean standard deviation and variance of the sky values measured in these individual regions, respectively, we obtain

$$\Delta I_{\text{sky}, \lambda}^2 = \frac{\langle \sigma_{\text{sky}} \rangle^2}{N_{\text{isophote}}} + \max \left( \sigma_{\langle \text{sky} \rangle}^2 - \frac{\langle \sigma_{\text{sky}} \rangle^2}{N_{\text{region}}}, 0 \right). \quad (4)$$

# • Step 6: find out the bulge position

- use eyes to get the initial bulge\_locaion and initial break\_lo
- To be more reliable and less subjective, move the bulge\_position inward and outward ( smallest major axis to initial break ), the fitting slope doesn't change much when it's outer than the bulge\_lo ( I will introduce the fitting process later )

- Step 7: use mpfit to fit the profile with single exponential and double exponential function
  - Fitting scale: outside the bulge location & inside of the total error less than 0.3 mag
  - Initial fitting value of break\_lo: two point outer than bulge, +0.5Re, ..., inside of error less than 0.3 mag, choose the result with the smallest chi<sup>2</sup>
  - Selecting criterion: 1: smaller AIC ( $2k + n \cdot \chi^2$  value)
    - k: number of variable n: amount of data point
    - 2: residual distribution without systematic trend (more important)
  - Double fitting tells the break position
  - By now, we first choose galaxies with  $\tan(\theta) > 0.2$  (theta: angle between inner fitting line and outer fitting line), more obvious, easier to analyze
